

## 22 SPRING CSCE 629 600: ANALYSIS OF ALGORITHMS - Homework 4

Name: Rohan Chaudhury

UIN: 432001358

**Question (1) Textbook page 630, Exercise 23.1-6.**

**Show that a graph has a unique minimum spanning tree if, for every cut of the graph, there is a unique light edge crossing the cut. Show that the converse is not true by giving a counterexample.**

**Answer:**

Let us try to show the proof with a contradiction.

For that, we will assume that there exists 2 Minimum Spanning Trees  $T$  and  $T'$  which are distinct from each other for a graph  $G=(V, E)$  which has a unique light edge crossing the cut for every cut of the graph. Let an edge  $e_1$  be in  $T$  and not in  $T'$ .

Now, if we remove the edge  $e_1$  from the tree  $T$ , it will cut the tree into 2 different components/trees with vertices  $V_1$  and  $V_2$  which contained the edge  $e_1$ . Now, let us consider this cut between  $V_1$  and  $V_2$  as  $(V_1, V_2)$ . Let the unique light edge crossing the cut  $(V_1, V_2)$  be  $x$ .

Now, if  $e_1 \neq x$ , then, the edge weight of  $x$  is less than the edge weight of  $e_1$  since  $x$  is the unique light edge crossing the cut  $(V_1, V_2)$ , and the spanning tree  $T \cup (x) - (e_1)$  (i.e., the spanning tree  $T$  with edge  $e_1$  removed between vertices  $V_1$  and  $V_2$  and edge  $x$  added between the vertices  $V_1$  and  $V_2$ ) has lesser total edge weight than  $T$  which contradicts our assumption that  $T$  is a minimum spanning tree of  $G$ .

So, we have to assume that  $e_1 = x$ . That means that the unique light edge  $x$  crossing the cut  $(V_1, V_2)$  is not a part of the minimum spanning tree  $T'$  as we had initially assumed that edge  $e_1 (=x)$  is not in  $T'$ . Now, let us consider the path between vertices  $V_1$  and  $V_2$  for  $T'$  which must be connected by an edge  $e_2$  in  $T'$  crossing the cut  $(V_1, V_2)$ . Now, as established, since  $e_1$  is a unique light edge crossing the cut between  $V_1$  and  $V_2$ , the edge weight of  $e_1$  must be less than the edge weight of  $e_2$ . So, if we remove  $e_2$  from  $T'$  and add  $e_1$  between the vertices  $V_1$  and  $V_2$  in  $T'$  (i.e, the spanning tree  $T' \cup (e_1) - (e_2)$ ) then

the resulting spanning tree must have a lesser total edge weight than  $T'$  which contradicts our assumption that  $T'$  is a minimum spanning tree of  $G$ .

Hence,  $e_2 = x = e_1$ , so our initial assumption that edge  $e_1$  is not in MST  $T'$  is not valid. Since  $e_1$  is chosen at random, so this is a general case for all the edges in  $T$  and  $T'$ . Hence, both the minimum spanning trees are the same and the graph has a unique minimum spanning tree if, for every cut of the graph, there is a unique light edge crossing the cut.

### **A counterexample for the above:**

We have to show that a graph can contain a unique minimum spanning tree even if it doesn't have a unique light edge crossing the cut for every cut of the graph.

Let us consider the following graph and the following cut given in the color red:

The graph has vertices  $A, B, C$ , and edge weights of edges  $(A, B)$ ,  $(B, C)$ , and  $(A, C)$  is 2, 5, 2 respectively as shown. This graph has a unique minimum spanning tree containing the edges  $(A, B)$  and  $(A, C)$  however the cut shown in red between the vertex  $A$  and edge  $(B, C)$  doesn't have a unique light edge crossing the cut (both edges  $(A, C)$  and  $(A, B)$  crossing the cut have edge weight equal to 2).

**Hence this serves as a counterexample that shows that a graph can contain a unique minimum spanning tree even if it doesn't have a unique light edge crossing the cut for every cut of the graph.**

In fact, this holds true for any set of edge weights in the above graph such that:

$w(A, B) = w(A, C)$ ,  $w(B, C) > w(A, B)$ , and  $w(B, C) > w(A, C)$ ,

where  $w(X, Y)$  denotes the edge weight of edge  $(X, Y)$
